What's in a name?

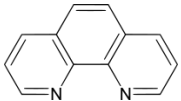

Nomenclature needs to provide basic information about the complex:

1. what is the metal? *obviously*
2. What is the oxidation state of the metal? *A little less obvious perhaps, but most transition metals have more than one*
3. Is the metal in the cation or the anion? *In a salt, the metal can be part of either or both*
4. What are the ligands? *Again, this is pretty obvious*
5. How many ligands are there? *Well, yes, of course...*
6. How are they arranged? *The geometric arrangement of the ligands plays a huge role in the properties of the complex and must be specified.*

How do we do this?

THE RULES:

1. In naming a salt, cation first, then anion (*no problem, that's just like genchem*)
2. To name a complex/ complex ion: two parts written together as one long word, ligands first, metal second
 - a. Greek prefixes denote "how many"
 - i. Mono-, di-, tri-....
 - ii. Bis, tris, tetrakis... (*used when the mono, di, tri names just won't do... e.g. when the ligand name itself already has a greek prefix in it, as in ethylenediamine*)
 - b. Ligand names in alphabetical order (*for consistency*)
 - i. Anionic ligands get -o ending, (i.e. Chloride, Cl⁻, becomes chloro)
 - ii. Neutral ligands simply keep the name of the

molecule, (e.g. phenanthroline, , with a few exceptions

1. NH₃ is ammine
2. CO is carbonyl

Inorganic Nomenclature Handout (for coordination/ organometallic compounds)

Created by Sheila Smith, University of Michigan- Dearborn (sheilars@umd.umich.edu) and posted on VIPER (www.ionicvipr.org) on January 25, 2012. Copyright Sheila Smith 2012. 3. H_2O is aquo
- iii. Arrangement of ligands should be specified
 1. Cis- (beside) vs. trans- (across)
 2. fac- (facial) vs. mer- (meridional - along an edge)
 3. Λ - vs. Δ - (for optical isomers)
- c. Metal name must include both the oxidation state and tell whether the metal is part of the cation or anion
 - i. Use parenthetical roman numerals to denote oxidation state (e.g. Fe^{3+} is iron(III))
 - ii. If the metal is part of an anion, add an -ate ending (e.g. Mn^{3+} in an anionic complex ion becomes manganate (III), for some metals the common root name is used as in ferrate (III) for Fe^{3+} in an anionic complex ion)

examples

$\text{K}_4[\text{Fe}(\text{CN})_6]$ - potassium hexacyanoferrate(II)

6 CN⁻ ligands, Fe²⁺ is in the anion, "ironate" just doesn't sound right so ferrate(II)

$[\text{Co}(\text{NH}_3)_6]\text{Cl}_3$

- hexaamminecobalt(III) chloride

6 ammonia ligands, Co³⁺... do not use "trichloride"... it's wrong for magnesium chloride (MgCl₂) and it's wrong here too

$[\text{Co}(\text{en})_3]\text{Cl}_3$

- trisethylenediaminecobalt(III) chloride

If the structure was given you would have to specify Λ or Δ here since this is optically active.

cis-diamminedichloroplatinum(II)
